Table, SDC 1: Cox proportional hazards models for appropriate functional form (hazard ratios, 95\% confidence intervals)

For all models, $\mathrm{n}=2,444$, time at risk $=5,913$ person-years and there were 458 seroconversions. All models contain indicator variables for year of observation (not shown). ${ }^{\dagger}$ Coefficients for squared, cubic and quartic terms represent 10,100 and 1000 unit change in the respective variables.

|  | Multiply imputed dataset | Complete case dataset | Missingness (\%) | Change (\%) in incidence rate ${ }^{* *}$ |
| :---: | :---: | :---: | :---: | :---: |
| All women aged 15-29 years old |  |  |  |  |

| Casual partner in past 12 months |  | 7.56 | - | 0.0 |
| Lowest condom use level in relationships in past 12 months |  | 7.49 | 0.9 | 0.9 |

* Missingness for covariates is the amount of person-time with missing values prior to imputation for each variable, as a proportion of the 7,722 years of person-time in the Multiply Imputed dataset. ** Change in the incidence rate comparing all person-time in the imputed dataset to all person-time in the complete-case dataset (in the top half of the table this is the complete-case dataset for all independent variables; in the bottom half it is the complete-case dataset for each individual variable).

The dataset for multiple imputation consisted of all person-time for which: (i) there was a valid HIV test result at the beginning and end of the observation period; (ii) the respondent had participated in the General Health module by the beginning of the period; and (iii) we were unable to exclude the possibilities that they had yet to reach their sexual debut (i.e. we excluded women who reported never having had sex, or who had never reported any sexual partner up to the beginning of the period). Practically, this meant adding to the complete case dataset observation time for which: (a) partner age-disparity data was missing ( 1,406 person-years); or (b) covariate information was missing (an additional 403 person-years).

Missing data were imputed 20 times using chained imputations. The chained imputation process used all variables included in analyses in this paper, plus several other variables that might be expected to be correlated with sexual and socio-demographic variables: urban/suburban/rural household; distance to nearest health clinic, major road, minor road, primary school and secondary school; Isigodi (traditional Zulu area) of household; currently economically active (yes/no); and year of visit.

Figure, SDC 3: Kaplan-Meier cumulative incidence curve for HIV incidence during follow-up, stratified by respondent's baseline age

For all models, $\mathrm{n}=2,972$, time at risk $=7,722$ person-years and there were 584 seroconversions All models contain indicator variables for year of observation (not shown). ${ }^{*}$ The coefficient on the variable "age squared" represents a 10 -unit change in this variable; the coefficient on the variable "age cubed" represents a 100 -unit change in this variable. $\dagger$ This model also contains indicator variables for age categories. A joint test for equality on the three age by age-disparity interaction terms was not statistically significant ( $\chi^{2}=1.42, \mathrm{p}$-value: 0.492 ).

| p-value | 0.22 | 0.01 | 0.62 | 1.00 |

Values are hazard ratios and 95\% confidence intervals from Cox proportional hazards models. This table contains summary results for 12 separate regression models (four outcome forms for each of three interacted covariates). For all models, $n=2,444$, time at risk $=5,913$ person-years and there were 458 seroconversions. All models contain indicator variables for year of observation, age of respondent (linear, quadratic and cubic terms centred at age 15) and all socio-demographic and behavioural covariates from the main analysis. Empty cells in this table reflect categories in which there were so few observed individuals with age-disparate partners that they had to be removed in order for models to converge.
