## Sample description

The households eligible for household interviews in the 2007 Demographic and Health Survey in Zambia were selected as follows: First, a stratified random sample of 320 clusters of households was drawn from an enumeration list of 16,757 household clusters, which had been previously used in the 2000 Census of Population and Housing of the Republic of Zambia. ${ }^{1}$ The 18 strata were defined by province and rural versus urban location. Second, a complete listing of all households in the 320 selected clusters was conducted, and a systematic sample of 8000 households was drawn. One cluster was excluded, leading to a sample of 7969 eligible households. In some households the interview could not take place because the household structure was no longer occupied, no eligible household member was present at the time of the fieldworker visit, or none of the present eligible household members consented to be interviewed with the Household Questionnaire (see Figure 1 in the article). ${ }^{1}$
"Any adult member of the household who is capable of providing information needed to fill in the Household Questionnaire" was eligible to serve as respondent for the Household Questionnaire. ${ }^{2}$ In the household interview, the respondent was asked to name all household members, and all visitors who had stayed at the household during the previous night, and to provide information on their sex and age. All men aged 15-59 years and all women aged 15-49 years "who were either permanent residents of the households in the 2007 ZDHS [Zambian Demographic and Health Survey] sample or visitors present in the household on the night before the survey were eligible" for the individual interview and HIV testing ( 7146 men and 7408 women). Figure 1 shows the samples used in HIV prevalence estimation in this study.

Eighteen men and seven women with known HIV status had missing information for at least one of the independent variables included in the contact regressions; an additional 80 men and 458 women with known HIV status had missing information for at least one of the independent variables included in the consent regressions (Figure 1 in the article). These individuals were thus not included in the respective selection and imputation models. Not being able to use information on these individuals in predicting HIV status of HIV survey non-participants does not result in bias or inconsistency in our results provided that the missing variables in the data, other than HIV status, are missing at random.

## HIV testing laboratory procedures

After obtaining consent, interviewers used a sterile finger-prick lancet to collect a dried blood spot (DBS) sample on a filter paper card. HIV status was determined by antibody testing with an initial enzyme-linked immunoabsorbent assay (ELISA) test (Vironostika HIV Uni-Form II Plus O, Biomerieux), followed by a confirmatory ELISA (DADE Behring HIV-1/2) if the initial result was HIV-positive. ${ }^{1}$

## Plausibility check of estimated HIV prevalence in men

We tested the plausibility of the finding in our selection model that HIV prevalence in men who did not consent to HIV testing was higher than in survey participants by dividing the 34 interviewers (including the 'interviewer' we assigned to all interviewers with fewer than 50 individual interviews) into 17 'more successful' ones (i.e. an interviewer with a consent rate above the median of 0.804 ) and 17 'less successful' ones (i.e. an interviewer with a consent rate
below 0.804 ). The mean consent rate among 'less successful' interviewers was $73.9 \%$ compared to $85.6 \%$ among 'more successful' interviewers. We then compared the HIV prevalence rate found by 'more successful' versus 'less successful' interviewers. 'More successful' interviewers found significantly higher HIV prevalence (14.6\%) than 'less successful' interviewers ( $10.6 \%$, $P$-value of difference $<0.001$ ). We can think of 'more successful' interviewers as obtaining consent to an HIV test from the same types of men as 'less successful' interviewers, plus from an additional $11.7 \%$ of men who usually do not consent when the interviewer is 'less successful'. If this is the case, the observed prevalence rate in the population is the weighted average of the prevalence rate in men who usually consent and those men who consent only to 'more successful' interviewers. The prevalence rate $x$ among those $11.7 \%$ of men who only consent when their interviewer is 'more successful' solves the equation
$0.146=\frac{0.117 * x+0.739 * 0.106}{0.117+0.739}$
i.e. a prevalence rate $x$ of $40.0 \%$. This calculation suggests that there must be a very high prevalence rate among men who usually refuse to test but agree to test with a 'more successful' interviewer.

## Identification of valid exclusion restrictions

In general, the identification of a valid exclusion restriction involves three steps. First, the researcher must consider which of the variables available in a survey could be associated with survey participation. Second, she must discard variables that could have affected the outcome of
interest. This second test will eliminate the overwhelming number of variables. For instance, most respondent or household characteristics recorded in the Demographic and Health Surveys could conceivably have affected HIV status. In addition to the exclusion restrictions used in this study, we did not identify any other plausible selection variables in the Zambia 2007

Demographic and Health Survey. However, in other surveys and contexts other variables than those used in this study may be plausible selection variables. Detailed knowledge of the mechanisms of particular HIV surveys will be helpful in the search for such variables. Differences in time or space in survey conditions or operating procedures may affect contact rates (such as the weather or the types of vehicles fieldworkers use when looking for eligible participants) or consent rates (such as the availability of alternative HIV testing services or incentives for survey participation) without determining HIV status independent of the selection effect. Third, the researcher must test whether the plausible selection variable is indeed significantly associated with survey participation in a selection model, controlling for other observed variables. In the case of multiple dummy variables representing different categories of the same concept, such as interviewer identity, the relevant test for this purpose is one of joint significance of all selection variables.

## Limitations of Heckman-type selection models

The Heckman-type selection models used in this study assume that the error terms follow a bivariate normal distribution. ${ }^{3}$ Future extensions of this work could include relaxation of this distributional assumption in non-parametric selection models. Furthermore, while some of the imputation approaches assuming "missing at random" can simultaneously predict missing values in any number of variables, ${ }^{4}$ Heckman-type selection models can only be used to predict values
of the outcome variable. While this condition may be a disadvantage when many variables suffer from large proportions of missing values, in the case of HIV surveys the outcome variable of principal interest, HIV status, is commonly the one variable with the largest proportion of missing values, while only small proportions of explanatory variables (such as sex, age, and education) are missing. Heckman-type selection models are thus likely to be appropriate approaches to control for non-participation in many HIV surveys.

eTABLE 2: Consent regressions (women): table subtext
$d y / d x=$ marginal effects evaluated at the sample mean; the effects are expressed as absolute change in the probability of HIV-positive status. For dummy variables, the marginal effects represent the probability change in response to the discrete change of the dummy variable value from zero to one. All confidence intervals (Cl) are based on standard errors that are adjusted for clustering at the level of the Demographic and Health Survey cluster. In addition to the variables shown, the imputation model and each of the two equations in the selection model include dummy variables for language, ethnicity, religion and region. The HIV survey participation equation further includes dummy variables for interviewer identity. See eTables 5A and 5B for effect estimates for the variables not shown in this table.

$d y / d x=$ marginal effects evaluated at the sample mean; the effects are expressed as absolute change in the probability of HIV-positive status. For dummy variables, the marginal effects represent the probability change in response to the discrete change of the dummy variable value from zero to one. All confidence intervals (CI) are based on standard errors that are adjusted for clustering at the level of the Demographic and Health Survey cluster. In addition to the variables shown, the imputation model and each of the two equations in the selection model include dummy variables for region. The HIV survey participation equation further includes dummy variables for household visit on the first day of fieldwork in the cluster and for interviewer identity. See eTables 7A and 7B for the variables not shown in this table.

$d y / d x=$ marginal effects evaluated at the sample mean; the effects are expressed as absolute change in the probability of HIV survey participation. The marginal effects represent the probability change in response to the discrete change of the dummy variable value from zero to one. All confidence intervals (CI) are based on standard errors that are adjusted for clustering at the level of the Demographic and Health Survey cluster.

$\mathrm{dy} / \mathrm{dx}=$ marginal effects evaluated at the sample mean; the effects are expressed as absolute change in the probability of HIV survey participation or HIV-positive status. The marginal effects represent the probability change in response to the discrete change of the dummy variable value from zero to one. All confidence intervals (CI) are based on standard errors that are adjusted for clustering at the level of the Demographic and Health Survey cluster.
